### Geocoding: What is it?

Geocoding is the process of converting addresses (like “1600 Amphitheatre Parkway, Mountain View, CA”) into geographic coordinates (like latitude 37.423021 and longitude - 122.083739), which you can use to place markers on a map, or position the map.

### Geocoding in the NLP Suite

The NLP Suite provides two free approaches to geocoding locations, via Nominatim and via Google. These options are available from GIS\_main.

Other NLP Suite scripts (e.g., GIS\_Google\_Earth\_main, SVO\_main), also have geocoding capabilities. GIS\_Google\_Earth\_main and SVO\_main rely on Nominatim as the default

geocoding option. If you wish to use Google for geocoding, please, use the GIS\_main script.

**Whichever option is chosen for geocoding (Nominatim, Google) the NLP Suite will carry out the geocoding automatically. But... other options are available. See below.**

### *Nominatim*

Nominatim is an open-source, freeware geocoding tool. Nominatim uses OpenStreetMap data to find locations on Earth by name and address (geocoding) (see below for additional information on OpenStreetMap). Nominatim can also do the reverse, find an address for any location on the planet.

Nominatim is the default geocoding option when running the GIS\_main script.

### *Nominatim limitations*

If the Nominatim geocoder service exits with the error “**too many requests**,” you can break up the csv location file and process each subfile for geocoding as normal csv files.

### *Google*

When you select the Google geocoding tool the API key widget will be displayed. You will need to enter there the free Google API key (see the TIPS on Google API).

You will need to enter the API key only once. From then on, the Suite will use the saved key when you selected Google as the preferred geocoding tool.

### *Google limitations*

With the basic Google Earth or Google Maps, you can find only one location at a time by typing its physical address or geographic coordinates (latitude and longitude) into the search box. **Google Earth Pro lets you import up to 2,500 locations at a time.** For larger datasets, you can break up the location data into batches of 2,500 items or less, then import each batch separately. To perform batch geocoding, you need to have the addresses or coordinates in one or more .csv (comma separated values) or .txt (plain text) files. You can export such files from Microsoft Excel and other spreadsheets. Check the “Importing Addresses” section of the Google Earth help documentation for information about formatting these files.

### *Faulty geocoding results and how to deal with it*

Whether you use Google or Nominatim as your geocoding tool, after the geocoding and

mapping is done, please, check carefully the results. If you are geocoding locations such as Athens or Rome in Georgia, most likely they will be geocoded in Greece and Italy. If you specify the United States as the country bias, the geocoder may select Rome, New York, or Indiana, or Illinois, rather than Georgia. To make sure the geocoded Rome is in Georgia, you may need to edit the geocoded csv file, adding Georgia as the state, e.g., Rome, Georgia.

### **Databases/Gazetteers**

There are also freeware available databases that one can download and then search for waypoints or build an application that can read an Excel file and batch geocode. The problem with these databases is that waypoints are given in decimal degrees and these will need to be converted since most GIS programs do not work with decimal waypoints. You are better off using the applications listed above and that, in any case, rely on the databases listed here.

#### ***OpenStreetMap***

<http://www.openstreetmap.org/about>

OpenStreetMap is the database used by **OpenRefine**, and many other applications.

#### ***GeoNames***

The **GeoNames** geographical database covers all countries and contains over eight million placenames that are available for download free of charge. See the GeoNames website at <http://www.geonames.org/>

#### ***WhosisOnFirst***

**WhoIsOnFirst** is an online system for developers that is attempting to eliminate some of the errors in the previous two databases (<https://whosonfirst.org/>).

### **Further geocoding options**

#### ***Google Maps***

**Google Maps** provides an API that will do geocoding for you via an HTTP request, where an API is an Application Programming Interface, i.e., a set of routines, protocols, and tools for building software applications.

[https://developers.google.com/maps/documentation/geocoding/intro?utm\\_source=google&utm\\_medium=cpc&utm\\_campaign=2015-Geo-NA-GEO-MAB-GoogleSearchDev&utm\\_content=NBINNPSGeocoding&utm\\_term=dev&gclid=CIWdgpOUv8gCFdgRgQodnMgAlw](https://developers.google.com/maps/documentation/geocoding/intro?utm_source=google&utm_medium=cpc&utm_campaign=2015-Geo-NA-GEO-MAB-GoogleSearchDev&utm_content=NBINNPSGeocoding&utm_term=dev&gclid=CIWdgpOUv8gCFdgRgQodnMgAlw)

#### ***Google Earth Pro***

## Google Earth Pro (<http://www.google.com/earth/>)

In January 2015, Google made available for free its Google Earth Pro. You can download it at <http://www.google.com/earth/download/gep/agree.html>

**Note:** Google Earth Pro requires a license key. If you do not have a key, use your email address and the key **GEFPFREE** to sign in.

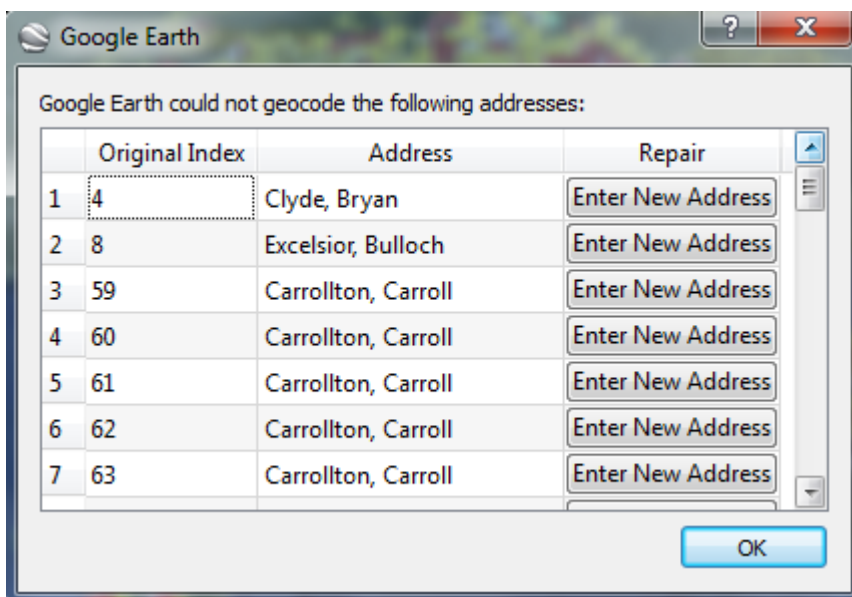

The software runs on computers with Windows (XP and later) and Apple (OS X v. 10.6.0 or later) operating systems.

From the Google Earth Pro menu, click on File and then Import to open a dialog box that let us select the file with the addresses. The Data Import Wizard lets you verify that the .csv or .txt file structure was correct. If the data contains latitude/longitude information, users would click Next to go to a second page, where they'd verify that the proper latitude/longitude fields have been selected.

**Otherwise, click the checkbox “This dataset does not contain latitude/longitude information, but street addresses”, then click Next.**

At the end of the geocoding process, you may get a form that displays all records that could not be geocoded

You will then get a progress form for data import

When errors are encountered, Google Earth will display the following message:

Features of Google Earth and Google Earth Pro		
Features	Google Earth	Google Earth Pro
Print images	Screen resolution only	High resolution (up to 4800 x 3200 pixels)
Regionate large datasets	No	Yes
Batch geocode addresses	No	Automatically Geo-locate up to 2500 at a time
Import GIS data	No	ESRI shapefiles (.shp) and MapInfo (.tab) files
Import GIS images	Manually geo-locate	Automatically geo-locate
Import large image files	Up to max texture size	Super Image Overlays when larger than max texture size
Access demographic, parcel, and traffic data layers	No	Yes
Create premium movies	No	HD 1920 x 1080 pixels
Measure area of a polygon or circle	No	Yes
Map multiple points at once	No	Yes
Viewshed tool	No	Yes
Map-making tool	No	Yes

**Table 1. Comparison of some key features of Google Earth and Google Earth Pro.**

## ***OpenRefine***

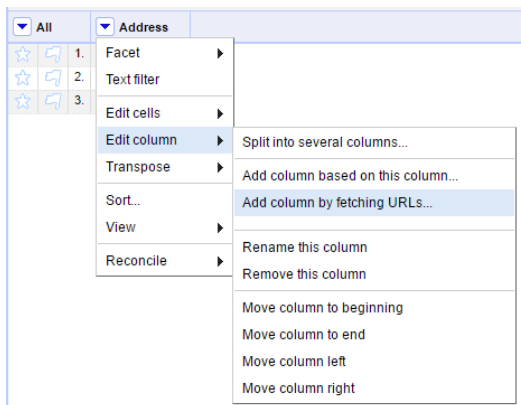

OpenRefine (<http://openrefine.org/>) allows you to geocode using the Google Geocoding API.

To do so, first import a file with at least the list of addresses you wish to geocode. OpenRefine supports the following file formats: TSV, CSV, \*SV, Excel (.xls and .xlsx), JSON, XML, RDF as XML, and Google Data documents.

We have imported a list of three cities in Georgia that we'd like to geocode. It is important that both city and state are listed together in the same column formatted as: City, State

▼ All	▼ Address
★	1. Macon, Georgia
★	2. Atlanta, Georgia
★	3. Duluth, Georgia

Now, click on the arrow in the column containing your addresses with the City, State format and select **Edit column > Add column by fetching URLs...**

In the form that pops up, give your new column a name such as “geocodingResponse”. Paste the following into the “Expression” box:

```
"http://maps.google.com/maps/api/geocode/json?sensor=false&address=" +
escape(value, "url")
```

### Add column by fetching URLs based on column Address

with(value.parseJson().results[0].geometry.location, pair, pair.lat +", " + pair.lng)

1.

{ "results": [ { "address\_components": [ { "long\_name": "Macon", "short\_name": "Macon", "types": [ "locality", "political" ] }, { "long\_name": "Bibb County", "short\_name": "Bibb County", "types": [ "administrative\_area\_level\_2", "political" ] }, { "long\_name": "Georgia", "short\_name": "GA", "types": [ "administrative\_area\_level\_1", "political" ] }, { "long\_name": "United States", "short\_name": "US", "types": [ "country", "political" ] } ], "formatted\_address": "Macon, GA, USA", "geometry": { "bounds": { "northeast": { "lat": 32.8997851, "lng": -83.54859789999999 }, "southwest": { "lat": 32.765651, "lng": -83.7397409 } }, "location": { "lat": 32.8406946, "lng": -83.6324022 }, "location\_type": "APPROXIMATE", "viewport": { "northeast": { "lat": 33.8876179, "lng": -83.54859789999999 }, "southwest": { "lat": 32.765651, "lng": -83.7397409 } } }, "place\_id": "ChIJDeOBIEv484gRoas\_8Tx9se4", "types": [ "locality", "political" ] } ], "status": "OK" }

OK

Cancel

Hit OK. You will now have a third column containing the coordinates of your addresses. To clean up further, you can remove the geocodingResponse column (**Edit column > Remove this column**) to get the final result:

▼ All	▼ Address	▼ latlng
☆	1. Macon, Georgia	32.8406946, -83.6324022
☆	2. Atlanta, Georgia	33.7489954, -84.3879824
☆	3. Duluth, Georgia	34.0028786, -84.1446376

If you wish to have latitude and longitude in separate columns, you can do so by going to **Edit column > Split into several columns...**

The comma serves as the delimiter, so you can leave the settings as they are and hit OK. OpenRefine will then split the “latlng” column into two columns, labeled “latlng 1” and “latlng 2”. You can rename them for clarity (**Edit column > Rename this column**), such as in the following screenshot:

▼ All	▼ Address	▼ lat	▼ lng
☆	1. Macon, Georgia	32.8406946	-83.6324022
☆	2. Atlanta, Georgia	33.7489954	-84.3879824
☆	3. Duluth, Georgia	34.0028786	-84.1446376

You can then export this data to various formats:

## ***CartoDB & QGIS***

You can also use a combination of CartoDB and QGIS (both free software) to geocode placenames and export coordinates, respectively. CartoDB is a web-based map-making and GIS analysis software that is free to use for the task at hand.

### ***Geocoding in CartoDB***

Open the CartoDB website ([link](#)) in your default browser. Create a free account and you will enter a page similar to this:

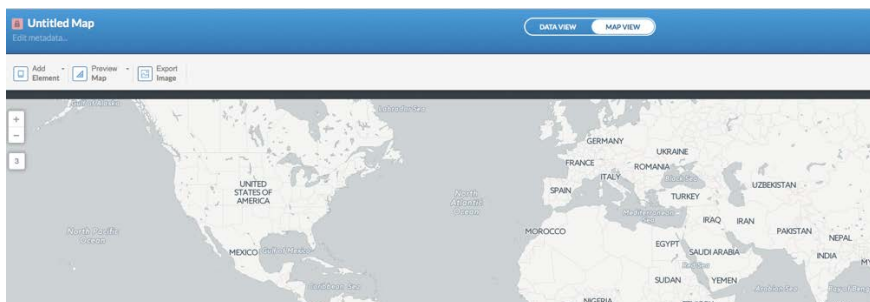

You can now import a csv file with the locations to be geocoded into CartoDB. Either drag and drop the spreadsheet onto this page or select **New Map** and **Connect Your Dataset**.

**\*\*Note\*\*** If you already have a CartoDB account with existing datasets/maps, then select **New Map** at the top right of the screen and follow the instructions above.

Either way, once your spreadsheet is uploaded into CartoDB you will be shown blank world map in the **Map View** and your spreadsheet in the **Data View**.

The map is blank because your spreadsheet/data is not georeferenced (creating latitude/longitude points based on locations, in this case, city names).

To Georeference your data, go to the **Edit** button at the top right of the page and select **Georeference Layer**. Once there you will enter a new screen. This is where you will specify which columns to link to geographic coordinates.

Georeference your dataset  
Transform your data into coordinates

No georeferenced data on your layer. If you don't georeference your data your map will be blank.

Lon/Lat Columns **City Names** Admin. Regions Postal Codes IP Addresses Street Addresses

Select the columns containing your Lon/Lat columns  
The selected columns are transformed into georeference coordinates.

1 Select Your Longitude

2 Select Your Latitude

Go to the **City Names** tab and then select the column where the city names are located, enter the state name in the **Admin Region** field and Country name in the **Country** field. The more fields you can fill out, the more accurate your georeferencing will be.

Georeference your dataset  
Transform your data into coordinates

No georeferenced data on your layer. If you don't georeference your data your map will be blank.

Lon/Lat Columns **City Names** Admin. Regions Postal Codes IP Addresses Street Addresses

Select the column that contains the City's Name  
No matter the type of the columns you select, we will transform them to number for georeferencing.

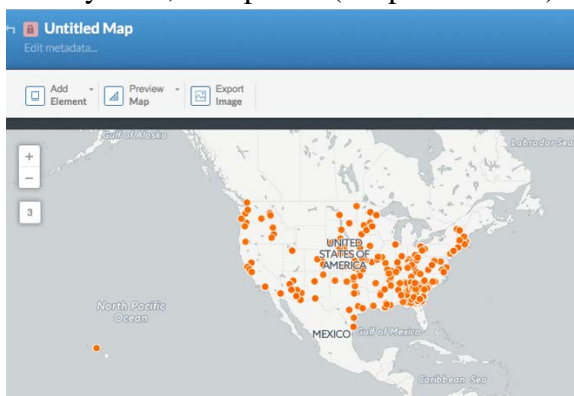

1 In Which Column Are Your City Names Stored?

2 Admin. Region Where City's Located, If Known

3 Country Where City's Located, If Known

Hit the **Continue** button at the bottom of the screen and select the **Georeference your data with points** option. CartoDB will then begin quickly georeferencing your spreadsheet.

Shortly after, data points (the place names) will now be layered over a world map.

Go back to the **Data View** at the top of the screen to view the actual dataset underlying the map. Your spreadsheet will now have values (lon/lat data) in the **the\_geom** column (2<sup>nd</sup> column)

**\*\*Note\*\*** When you first ingested your spreadsheet, the geom column existed, but had null values.

**Unfortunately, you cannot simply export the longitude/latitude data via a spreadsheet.** What you need to do is export the data in a shapefile. You can do this by hitting **Edit** in the top right of the screen and selecting **Export Layer**. Select SHP (shapefile) and download the zipped file. Unzip the file and you will have a folder with 5 files within. Make sure you keep the five files together in that folder. With that, we turn to the other software, QGIS.

Alternatively, if you would prefer not to use QGIS, you can export the data as a KML file and convert the KML to an Excel spreadsheet. This process is described in the “KML to Excel” TIPS file.

### *Geocoding in QGIS*

QGIS is a free, open-source GIS software that is an alternative to ArcGIS. It is useable on Windows, Macs and Linux. Here is the download link/instructions on how to download QGIS ([link](#)).

You can geocode data in QGIS but you will need to download and install the **plugin “mmqgis”**, which has batch geocoding capabilities.

You have the option of using either Google Maps or OpenStreetMap as the web service to locate an addresses, or cities, or states.

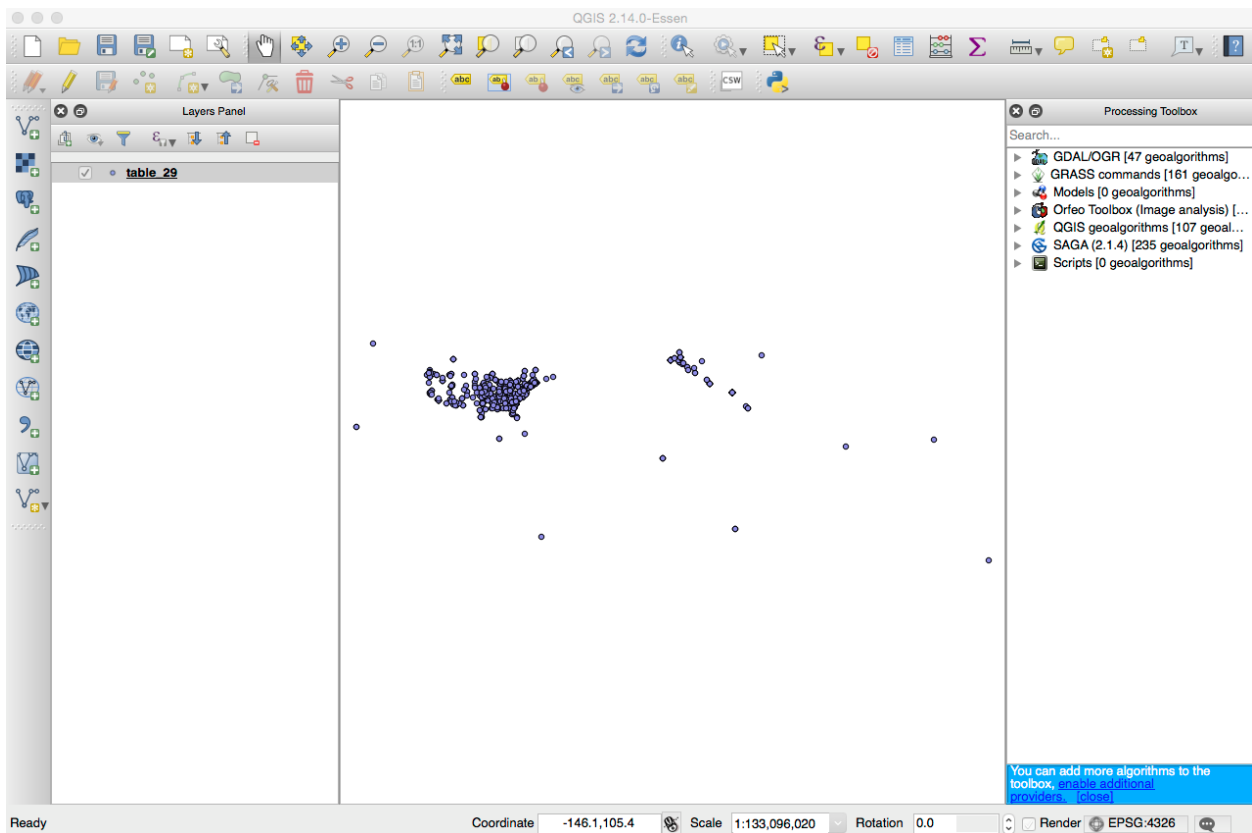

**Warning!!! Geocoding is VERY slow. Be patient!!! Most importantly, don’t give up thinking that QGIS has frozen up.**

### *QGIS – Exporting the Longitude/Latitude file from the Shapefile*

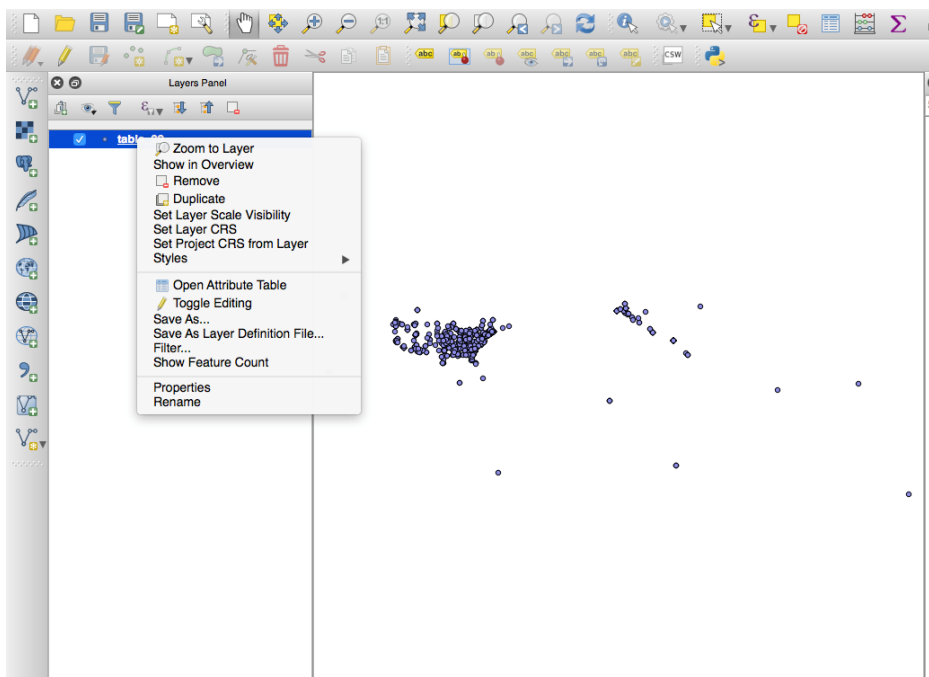

Once you have QGIS installed, open it. You should enter a blank home screen. Select **Add Vector Layer** from the left panel (highlighted in red)

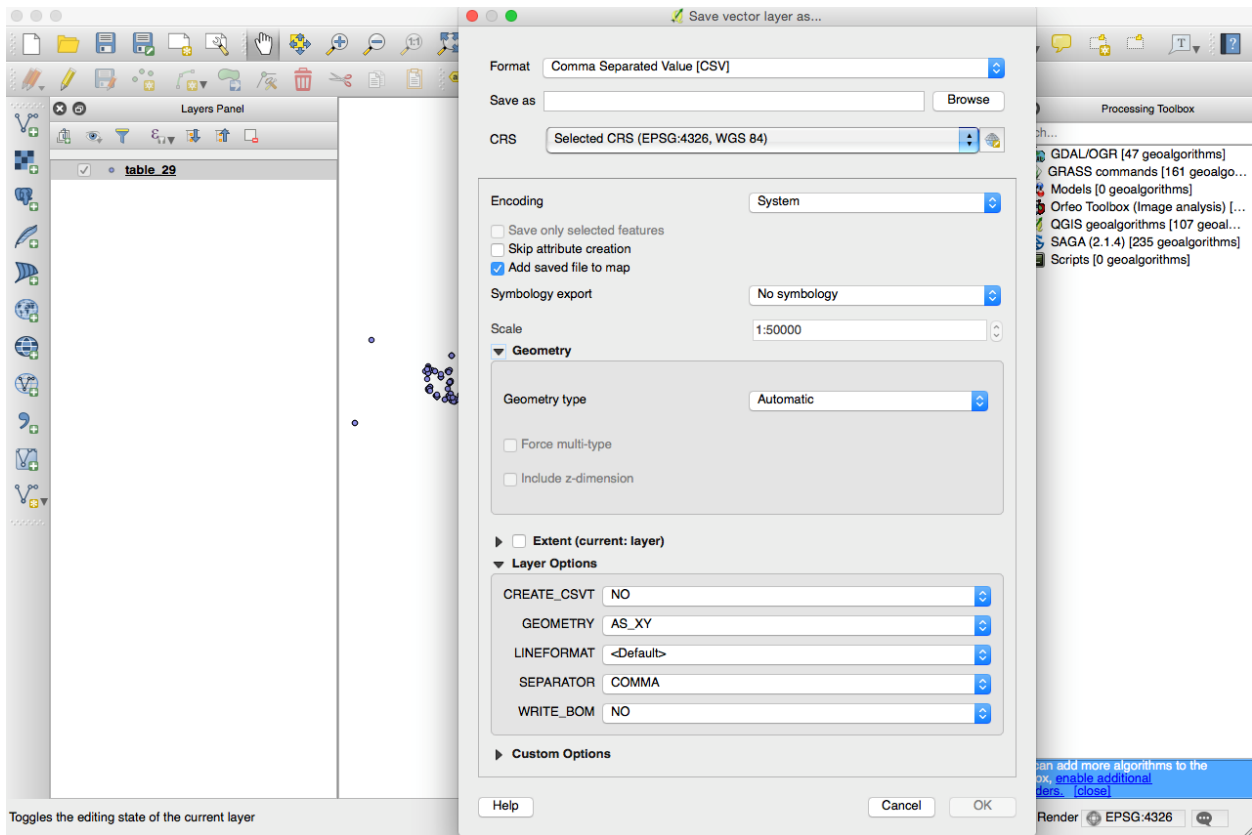

Select the shape file (file ending in .shp) you should get a screen like this.

What you want to do is right click the shape file on the left-side panel (in the screen above the filename is Table\_29) and select **Save As**

You can then select where you want to save the file on your computer. Make sure the settings are the same as in the screen below. It is important to save it as a CSV file.

When you open the newly created CSV file, you should see your latitude in the X Column (first column) and the longitude in the Y Column (2<sup>nd</sup> column).
